From Grammars to Ground Truth: A Unified Framework for Physics-Based Risk Calibration in Cyboquatic Machinery

Formalizing the Carbon Plane: From Mass-Load to Verified Net Flux

The formalization of the carbon plane represents a critical step in advancing the Cyboquatic ecosafety framework from an abstract conceptual model to a system grounded in verifiable physical principles. The current implementation correctly identifies `r_carbon` as a first-class coordinate within the `RiskVector`, signaling its structural importance . However, to elevate its status from a placeholder to a certified metric, it must be anchored in a rigorous, physics-based kernel that quantifies net CO_2-equivalent flux over an operational cycle. This process involves moving beyond the high-level concept of "CEIM mass-load" to a detailed formulation of material and energy balances, calibrated with empirical data and validated against established environmental modeling practices. The objective is to create a kernel where the `r_carbon` coordinate is a monotonic function of the machine's actual carbon footprint, ensuring that any deviation towards a less sustainable state necessarily increases the risk score.

The foundational concept for this formalization is the Environmental Impact Assessment (EIA), which provides methodologies for evaluating the potential environmental consequences of proposed projects or activities [22] [30]. Within this context, the mass-load calculation serves as a direct analogue to a material balance for a flow reactor. The formula $M_x = \int_{t_0}^{t_1} (C_{in,x} - C_{out,x}) Q_t \, dt$ provides a robust template for quantifying the net accumulation or depletion of a substance, in this case, carbon equivalents . To apply this, the industrial machinery must be modeled as a system with defined inputs and outputs. Inputs (`C_in`) would include the embodied carbon from feedstocks, raw materials, and energy sources, while outputs (`C_out`) would encompass all forms of carbon emissions, including direct combustion products (CO_2, CH_4), fugitive emissions, and off-gassing from processes [18] [85]. The integration over time (`dt`) captures the dynamic nature of these flows during a typical operational cycle, and the volumetric flow rate (`Q_t`) acts as a weighting factor, reflecting the scale of the process at any given moment. This approach aligns with predictive models used for embodied carbon in

building design phases and industrial carbon emission forecasting, both of which rely on detailed accounting of carbon stocks and fluxes [18] [20].

To ground this theoretical model in reality, a multi-source data strategy is essential. For `C_in`, data can be drawn from lifecycle assessment (LCA) databases and literature on sustainable carbon sourcing, such as the Clean Industrial Deal initiatives that promote the use of alternative carbon feedstocks [85]. For `C_out`, sensor data from Phoenix pilot systems is paramount. This includes continuous monitoring of fuel consumption rates, air quality sensors measuring stack gas concentrations, and data from IoT platforms tracking energy usage in real-time [50]. Furthermore, academic literature on soil organic carbon estimation under extreme climatic phenomena provides insights into modeling complex biogeochemical cycles that might be relevant if the machinery interacts with terrestrial ecosystems [2]. The calibration of this model requires correlating the calculated net carbon load with measured atmospheric concentrations, isotopic signatures, or other external benchmarks. The goal is to establish confidence intervals around the model's predictions, acknowledging that uncertainty is a key component of the risk profile itself.

The next layer of formalization involves translating the calculated net carbon mass into the normalized `r_carbon` coordinate, which must be mapped into the unified Lyapunov residual $V_t = \sum_j w_j r_j^2$. This mapping is governed by the corridor bands defined in the `CorridorSet`. The calibration of these bands—`carbon_safe_max`, `carbon_gold_max`, and `carbon_hard_max`—is the most critical empirical task. These values must be set based on scientifically defensible thresholds. For example, a `carbon_hard_max` could correspond to the maximum allowable carbon intensity for a given industrial sector, as defined by regulatory bodies or international agreements like those overseen by the UNFCCC [38]. A `carbon_gold_max` might represent a best-in-class performance target, achievable through optimized energy efficiency and the use of renewable or negative-carbon feedstocks. The `carbon_safe_max` would then sit below this, representing a margin of safety. The process of determining these band boundaries should involve sensitivity analysis of the underlying carbon flux model, Monte Carlo simulations to account for input uncertainties, and comparison with industry-wide averages. The ultimate proof required is that the function mapping net carbon load to `r_carbon` is monotonically increasing; as the net carbon output increases, the risk coordinate `r_carbon` cannot decrease. This ensures the system's logic is sound and prevents a scenario where a more polluting operational mode receives a lower risk score.

Finally, the entire process must be encapsulated within an executable artifact that can be integrated into a Continuous Integration (CI) pipeline. This would take the form of a dedicated Rust module within the Cyboquatic ecosystem, likely in a crate like

`cyboquatic_ecosafety_planes`. This module would contain functions for: 1. Calculating the net carbon mass-load using the `∫(C_in - C_out) Q_t dt` formula, consuming time-series data from sensors. 2. Normalizing the resulting mass into the `[0,1]` range for `r_carbon` based on the pre-calibrated corridor bands. 3. Unit tests that formally verify the monotonicity property of the normalization function. This executable kernel, when paired with cert-ready documentation, provides a complete and auditable solution for the carbon plane. The documentation would feature hex-stamped identifiers linking the mathematical definition of `r_carbon`, its monotonicity proof, and the specific corridor values to their corresponding lines of Rust code and rows in the associated ALN schema file (e.g., `carbon_corridors.aln`). This dual-output approach—executable artifacts for verification and documented proofs for certification—directly addresses the research goal of producing assets ready for audit and deployment. The result is a carbon plane that is not just conceptually present but is deeply integrated, empirically validated, and mathematically sound, contributing reliably to the overall KER triad and the Lyapunov stability argument.

Component	Description	Rationale & Source
Net Carbon Load Calculation	Employs a mass-balance integral: $M_{net_{carbon}} = \int_{t_0}^{t_1} (C_{in,carbon} - C_{out,carbon}) Q_t \, dt$.	Analogous to Environmental Impact Assessment (EIA) material balances [22] [30]. Basis for quantifying net carbon flux.
Data Requirements	Sensor data (fuel/energy use, emissions), LCA data (embodied carbon), process parameters (flow rate `Q_t`).	Necessary to populate the variables in the mass-load equation. Sources include Phoenix pilots, IoT platforms [50], and sustainability databases [85].
Normalization Kernel	Maps the calculated `M_net_carbon` to the normalized risk coordinate `r_carbon` ∈ [0,1].	Implemented via piecewise linear mapping based on calibrated corridor bands (safe, gold, hard). Ensures unit consistency for the Lyapunov residual.
Corridor Band Calibration	`carbon_hard_max` corresponds to regulatory limits [38]; `carbon_gold_max` to best-in-class targets; `carbon_safe_max` to a safety margin.	Based on scientific literature, industry standards, and stakeholder-defined goals for carbon negativity.
Executable Artifact	Non-actuating Rust module with functions for calculation, normalization, and unit tests for monotonicity.	Enables CI-runnable verification. The test proves that increased net carbon load always results in a higher or equal `r_carbon`.
Cert-Ready Documentation	Hex-stamped proofs linking the formula, corridor values, and code lines.	Provides auditable traceability for certification purposes, fulfilling the dual-output requirement of the research goal.

Grounding the Materials Plane: Kinetic Decay Models and Monotonicity Proofs

The materials plane, currently represented by the `r_materials` coordinate in the `RiskVector`, requires a similar transition from a generic risk placeholder to a rigorously defined metric rooted in chemical kinetics and ecotoxicology . The existing `MaterialKinetics` struct correctly identifies key parameters like `t90_days` (time to 90% mass loss), `r_tox` (normalized ecotoxicity), and `r_micro` (micro-residue risk) . The primary objective is to formalize the relationship between these parameters and the `r_materials` score, proving that the system penalizes materials that are persistent, toxic, or contribute to micro-pollution. This involves grounding the `t90` parameter in a first-principles kinetic model, establishing a convex aggregation function for the sub-parameters, and providing a formal proof of monotonicity for the entire `r_materials` calculation.

The cornerstone of this formalization is the adoption of a kinetic model for biodegradation. A widely applicable model is first-order decay, described by the differential equation $dS/dt = -k \cdot S$, where `S` is the mass of the substrate and `k` is the temperature-dependent reaction rate constant [42] [87]. The `t90` value, a central parameter in the existing framework, is directly derived from this rate constant: $t_{90} = \ln(0.1)/(-k)$. This provides a strong physics-based foundation for `t90`. More advanced Arrhenius-style models can further refine this by incorporating environmental factors like temperature (`T`), yielding an equation of the form $k = A \cdot \exp(-E_a/(R \cdot T))$, where `A` is the pre-exponential factor, `E_a` is the activation energy, and `R` is the gas constant [42]. This connection is crucial as it allows the `t90` value to be predicted under varying operational conditions, moving beyond a single-point measurement. Academic literature on accelerated weathering testing for plastics and polymers provides extensive guidance on experimentally determining `k` and validating these models, which can inform the development of the `t90` kernel [77] [78] [79].

With `t90` grounded in a kinetic model, the next step is to define the mapping from `t90` to a normalized coordinate `rt90`. This mapping must be proven to be monotonically decreasing: as the material becomes more persistent (i.e., `t90` increases), the normalized risk `rt90` must also increase. Given the formula $t_{90} = \ln(0.1)/(-k)$, and knowing that `ln(0.1)` is a negative constant, it follows that a smaller rate constant `k` (slower decay) results in a larger `t90`. The normalization function, likely a piecewise linear map based on corridor bands (e.g., `t90_hard_max = 180 days`), inherits this monotonicity. If `t90_hard_max` is exceeded, the material fails the corridor check, a principle already enforced at the trait level in the `AntSafeSubstrate` trait . This provides a clear,

provable link between the underlying chemistry and the high-level safety decision-making logic.

The full `r_materials` score is not solely dependent on persistence. It is a composite measure that aggregates multiple sub-risks, including ecotoxicity (`r_tox`), micro-residue formation (`r_micro`), leachate impact (`r_leach_cec`), PFAS-like residual risk (`r_pfas_resid`), and baiting potential (`caloric_density`) . To maintain the integrity of the Lyapunov framework, this aggregation must be convex. A simple weighted average is a suitable choice: $r_{materials} = \sum_i w'_i \cdot r_i$, where `w'_i` are weights for the sub-planes and `r_i` are the normalized scores for each sub-risk. The convexity of this function ensures that no single sub-risk can be "averaged out" by others, and that the total material risk score is a conservative estimate of the worst individual contribution. The weights (`w'_i`) can be tuned based on expert judgment and the relative importance of each hazard type. The monotonicity proof for the full `r_materials` score then becomes a straightforward extension of the single-parameter proofs: if any individual sub-risk (e.g., `r_tox`) increases due to a change in material composition, the aggregate `r_materials` score will also increase.

Similar to the carbon plane, this formalization must be delivered as a dual-product asset: executable artifacts and cert-ready documentation. An executable research artifact would be a Rust module containing: 1. A function to calculate `t90` from a set of kinetic parameters (e.g., `k` and temperature). 2. Functions to normalize each of the sub-parameters (`t90`, `r_tox`, etc.) into their respective `[0,1]` coordinates based on predefined corridor bands. 3. A function to compute the final `r_materials` score via the convex aggregation formula. 4. A suite of unit tests that provide formal proofs of monotonicity for each mapping function. For instance, one test would verify that calling the `rt90` normalization function with a larger `t90` value always produces a larger or equal output. The documentation would then serve as the certificate, hex-stamping each part of this mathematical chain—from the first-order decay equation to the final aggregation formula—and linking them to the corresponding source code files (e.g., `src/materials/t90.rs`, `src/materials/aggregation.rs`) and ALN schema rows defining the corridor bands (e.g., `alnspecs/materials.corridors.v2`). This creates an unbroken chain of custody from fundamental physics to high-level safety decisions, making the `r_materials` coordinate a truly trustworthy and verifiable component of the Cyboquatic framework.

Parameter	Role in `r_materials` Formalization	Mathematical Foundation & Proof of Monotonicity
`t90` (Time to 90% Mass Loss)	Primary indicator of material persistence. Inversely related to degradation rate.	Derived from first-order kinetics: $t_{90}=\ln(0.1)/(-k)$. Monotonic because a smaller rate constant `k` yields a larger `t90` [42] [87].
`r_tox`, `r_micro`, etc.	Sub-parameters representing specific hazards (toxicity, microplastics, etc.).	Normalized independently into [0,1] coordinates. Their monotonicity is inherent in their definition as normalized ecotoxicity scores [41].
`r_materials` Aggregation	Final composite score. Must be a convex function of its sub-components.	A weighted average, $r_{materials}=\sum w'_i r_i$, is a convex function. The proof is that the partial derivative of `r_materials` with respect to any `r_i` is a positive weight `w'_i`.
Executable Artifact	Rust module with kernels, normalization functions, and unit tests.	Tests provide formal proofs of monotonicity. CI pipeline can run these tests automatically on new material data.
Cert-Ready Documentation	Hex-stamped documents linking equations, corridors, and code lines.	Auditable trail from physics-based models to safety decisions, enabling certification of the `r_materials` plane.

Modeling the Biodiversity Plane: Habitat Connectivity Indices and Ecological Metrics

The formalization of the biodiversity plane presents the most significant interdisciplinary challenge, requiring the translation of complex ecological concepts into a computable risk coordinate, `rbiodiversity`. The core principle guiding this effort is that ecological connectivity—the unimpeded movement of species and the flow of natural processes—is fundamental to sustaining life on Earth [12] [16]. Therefore, the `rbiodiversity` coordinate should quantify how the operation of Cyboquatic machinery impacts this connectivity. The objective is to develop a kernel that calculates a `rbiodiversity` score based on a suite of ecological metrics, prove that this score is monotonically sensitive to changes in habitat quality, and integrate it into the Lyapunov framework in a way that is consistent with the other planes.

The selection of appropriate metrics is the first step. A comprehensive approach would draw from a variety of established connectivity metrics described in conservation planning literature [11]. Key indicators could include: 1. **Habitat Patch Characteristics:** The area, shape complexity, and edge-to-interior ratio of habitat patches affected by the machinery. Larger, more connected patches generally support higher biodiversity [13]. 2. **Landscape Connectivity Indices:** Measures that quantify the degree of network connectivity. Circuit theory, borrowed from electrical engineering, is a powerful method for modeling gene flow and animal movement across landscapes, effectively treating resistance to movement as analogous to electrical resistance [74] [76]. Other indices include

least-cost path analysis and connectivity indices that measure the probability of movement between patches [36]. 3. **Colonization and Disturbance Metrics:** Indicators of a site's ability to recover from perturbation, such as the proximity to source populations and the rate of natural succession. These metrics can be calculated using Geographic Information Systems (GIS) data, remote sensing imagery, and field survey data. The ALN shard schema already anticipates this by including fields like `ecoimpact_level`, which could be populated by these calculated indices .

Once a set of metrics is selected, they must be aggregated into a single, normalized `rbiodiversity` score that behaves predictably within the safety framework. The aggregation function must be proven to be monotonically *decreasing* with respect to harm. That is, any action that degrades habitat connectivity (e.g., creating a physical barrier, altering water flow patterns, causing pollution) must result in a decrease in the connectivity index and, consequently, a decrease in `rbiodiversity`. This is a critical logical requirement for the safety gate to function correctly. One approach is to use a principal component analysis (PCA) to reduce the dimensionality of the metrics and create a composite index, or to use a weighted sum where metrics known to have a strong negative impact on connectivity (like barrier creation) are given higher weights. The calibration of these weights and the normalization of the final score to the `[0,1]` interval would rely heavily on ecological modeling and expert consultation. Research on rapid evaluation of habitat connectivity change provides methodologies for this type of validation [15].

The practical implementation of this plane requires developing non-actuating diagnostic frames, as mentioned in the initial research objectives . These are computational modules that analyze spatial and temporal data to produce a `rbiodiversity` score without commanding any actuators. For example, a `BiodiversityImpactFrame` could take GIS layers of habitat types, hydrological models of altered flow paths, and land-use maps as input. It would then calculate the various connectivity indices and output a `rbiodiversity` coordinate. The monotonicity proof for this kernel would involve a formal argument based on the properties of the chosen aggregation function. For instance, if the aggregation uses a weighted sum, the proof would show that the partial derivative of `rbiodiversity` with respect to each harmful metric (e.g., barrier density) is negative, confirming that an increase in the metric leads to a decrease in the score.

As with previous planes, the deliverables are a dual product of executable artifacts and certifiable documentation. The executable artifact would be a Rust library containing the

`BiodiversityImpactFrame` and its dependencies. The certifiable documentation would be a crucial piece of evidence for any certification board. It would need to detail:

- The specific ecological metrics chosen and the rationale for their selection, citing sources like [11] and [12].
- The exact mathematical formula for the aggregation function.
- The process used to calibrate the corridor bands for `rbiodiversity` (e.g., low `rbiodiversity` corresponds to verifiable habitat fragmentation).
- A formal proof, likely embedded as comments or assertions in the code, demonstrating the monotonicity of the kernel.
- Hex-stamped references linking every claim in the document to specific lines in the Rust source code and rows in the associated ALN schema (e.g., `biodiversity_indices.aln`).

This rigorous documentation transforms the biodiversity plane from a qualitative concern into a quantitative, verifiable, and integral part of the Cyboquatic safety framework, ensuring that the machinery's impact on surrounding ecosystems is continuously monitored and managed according to the unified Lyapunov and KER semantics.

Metric Category	Example Metrics	Data Sources & Methodology	Connection to `rbiodiversity`
Habitat Structure	Patch Area, Shape Index, Edge Density	GIS vector data, Remote Sensing (e.g., satellite imagery) [13].	Larger, more contiguous patches generally support higher connectivity. Calculated using Morphological Spatial Pattern Analysis (MSPA) [14].
Connectivity Flow	Resistance Distance, Circuit Theory Conductance, Least-Cost Path Cost	Resistance surface models, landscape graphs [61].	Quantifies the ease of movement across a modified landscape. Higher resistance (lower conductance) implies lower connectivity.
Disturbance & Fragmentation	Barrier Density, Isolation Index, Contagion Index	GIS data on infrastructure, land-use maps.	Barriers and isolation directly impede movement, leading to population fragmentation.
Aggregation Function	Weighted Sum or PCA-derived Composite Score.	Weights assigned based on expert opinion or sensitivity analysis.	Creates a single, monotonic score. Must be proven that degradation of any underlying metric decreases the final score.
Proof of Concept	Simulation of habitat alteration (e.g., canal digging, wetland filling) followed by recalculating connectivity indices.	Use models like Circuitscape or GRASS GIS.	Demonstrates that the kernel correctly assigns a lower `rbiodiversity` score to the altered, less-connected landscape.

Calibrating the Hydraulics Plane: Surcharge Models and System Stress Analysis

The hydraulics plane, represented by the `r_hydraulic` coordinate, is designed to prevent system failure and environmental damage caused by excessive pressure, flow, or surcharge . The primary objective for this plane is to develop a physics-grounded kernel that accurately quantifies hydraulic stress and maps it to the `r_hydraulic` coordinate. This involves defining a "surcharge" metric based on fluid dynamics principles and calibrating its corridor bands using historical data from Phoenix pilot events and established hydraulic engineering models. The resulting kernel must be monotonic, ensuring that as system stress increases, so does the hydraulic risk score.

A robust starting point for the kernel is a normalized surcharge ratio. A simple yet effective formulation is presented in the preliminary analysis: $r_{\text{surcharge}} = \max(0, (HLR - HLR_{\text{safe}}) / (HLR_{\text{hard}} - HLR_{\text{safe}}))$. Here, HLR (Hydraulic Loading Ratio) is a dimensionless number representing the ratio of actual hydraulic loading to the system's designed capacity. This formula creates a piecewise linear map where the risk is zero if the HLR is below the `safe` threshold. As the HLR increases towards the `hard` threshold, the risk coordinate increases linearly. Once the HLR exceeds the `hard` threshold, the risk saturates at 1.0, indicating a violation. The physics behind this is intuitive: exceeding the hydraulic capacity of pipes, pumps, or treatment basins can lead to overflows, pipe bursts, and inefficient treatment—all of which are hazardous outcomes that the safety framework aims to prevent [26].

Calibrating the corridor bands (`HLR_safe` and `HLR_hard`) is the most critical empirical task. The `HLR_safe` value should be set well below the documented capacity limit of the physical components, incorporating a safety margin to account for transient events and aging of the infrastructure. The `HLR_hard` value should correspond to the point at which catastrophic failure or a major environmental release is likely. Historical data from Phoenix pilot operations is invaluable here. By analyzing logs of pump failures, valve malfunctions, or overflow events, it is possible to correlate specific HLR values with these adverse outcomes. This allows for a data-driven determination of the `HLR_hard` boundary. For more complex scenarios, hydrodynamic models like HEC-RAS can be used to simulate system behavior under various inflow conditions, helping to validate and refine these thresholds [33]. The broader field of flood risk assessment, which considers factors like slope, drainage density, and soil permeability, provides additional context for understanding system response to extreme events [25] [27]. The calibration process should aim to minimize false positives (unnecessary derating) while ensuring that all high-risk situations are detected.

More sophisticated hydraulic kernels can be developed by incorporating principles from open-channel flow and sediment transport. For instance, Manning's equation, which relates flow velocity to channel slope, roughness, and hydraulic radius, can be used to calculate the expected velocity under different loading conditions [31]. Deviations from expected velocities could serve as an alternative or complementary indicator of system stress. Similarly, models of sediment transport, which have shown accuracies around 86.7% in some studies, could be adapted to predict clogging risks in filters or pipelines, another form of hydraulic failure [29]. While the simpler surcharge ratio may be sufficient for the initial implementation, having these more detailed models available provides a pathway for future refinement.

As with all planes, the kernel must be implemented as an executable artifact and supported by certifiable documentation. The executable component would be a non-actuating Rust module, perhaps named `HydraulicStressFrame`, that takes real-time sensor data (pump speeds, valve positions, pressure gauges, flow meters) as input and outputs the `r_hydraulic` coordinate. This module would contain the logic for calculating the HLR and applying the piecewise linear mapping function. Crucially, it would also include unit tests that serve as a formal proof of monotonicity: the test would assert that for any two input states where the second has a higher hydraulic loading than the first, the resulting `r_hydraulic` is greater than or equal to the first.

The accompanying documentation would be structured to meet certification requirements. It would begin by stating the governing principle: preventing hydraulic system failure. It would then present the mathematical formula for `r_surcharge`, defining each term and referencing the source of the corridor band values. For example, it might state: "The `HLR_hard` corridor of 1.5 is derived from event log analysis of Phoenix pilot overflow incidents between 2023-2024." Finally, it would provide hex-stamped links to the Rust code implementing the kernel and the ALN schema defining the corridor values (e.g., `hydraulics.corridors.v2`). This combination of a simple, physically intuitive kernel, data-driven calibration, and rigorous formal verification makes the hydraulics plane a reliable and integral part of the Cyboquatic safety framework.

Aspect	Description	Rationale & Supporting Evidence
Kernel Formula	$r_{\text{surcharge}} = \max(0, (HLR - HLR_{\text{safe}}) / (HLR_{\text{hard}} - HLR_{\text{safe}}))$	A piecewise linear map based on Hydraulic Loading Ratio (HLR). Simple, interpretable, and directly prevents over-capacity events [26].
Corridor Calibration	`HLR_safe`: Safety-margin-adjusted component capacity. `HLR_hard`: Threshold for catastrophic failure, based on historical pilot data.	`HLR_hard` determined by correlating HLR with past failures (e.g., overflows). `HLR_safe` set conservatively below this. Validated with hydrodynamic models like HEC-RAS [33].
Physics Basis	Principles of fluid dynamics, specifically the relationship between flow rate, pressure, and system capacity.	Prevents phenomena like pipe bursts and inefficient treatment, which are direct consequences of exceeding hydraulic design limits.
Monotonicity Proof	Formal proof that the kernel's output is a monotonically non-decreasing function of hydraulic loading.	The numerator `(HLR - HLR_safe)` increases with HLR, while the denominator `(HLR_hard - HLR_safe)` is a positive constant. This guarantees monotonicity.
Executable Artifact	Non-actuating Rust module (`HydraulicStressFrame`) taking sensor data and outputting `r_hydraulic`. Includes unit tests for monotonicity.	Enables CI-runnable verification of the kernel's logic.
Cert-Ready Documentation	Hex-stamped document detailing the formula, corridor values, and links to code/schema.	Provides auditable evidence of the plane's design and calibration for certification boards.

Integrating the Data-Quality Plane: Uncertainty Quantification and Fail-Safe Logic

The data-quality plane, formalized through the coordinates `rcalib` and `rsigma`, addresses a critical but often overlooked aspect of system safety: the reliability of the information upon which control decisions are based. Treating poor data quality as a first-class risk is a sophisticated and necessary feature of a robust ecosafety framework. The objective is to develop a kernel that quantifies the uncertainty in sensor readings and calibration status, ensuring that this uncertainty is propagated through the system and can trigger fail-safe actions (Derate or Stop) even in the absence of a violation in any other risk plane. This plane acts as a meta-safety mechanism, protecting the entire system from being misled by faulty inputs.

The `rsigma` coordinate can be modeled as a direct measure of sensor noise. A practical implementation would be to calculate the standard deviation of a sensor's output over a short, rolling time window. A high `rsigma` indicates significant signal drift or random noise, suggesting the sensor may be malfunctioning or operating outside its specified accuracy. The `rcalib` coordinate can be a composite score reflecting the device's

calibration history. This could be based on factors like the time since the last factory or field calibration, the frequency of recent adjustments, and the magnitude of any applied correction factors. The existing `qpudatashardwriter` and `EcoNetSchemaShard2026v1` components are designed to capture this ingest-quality metadata, forming the basis for these calculations . The goal is to create a normalized score, `rsigma`, and a score, `rcalib`, both in the `[0,1]` interval, where higher values indicate worse quality.

The most profound contribution of the data-quality plane is its interaction with the Lyapunov stability argument. The unified residual is defined as $V_t = \sum_j w_j r_j^2$. By adding `rsigma` and `rcalib` as new terms in this summation—with their own weights (`w_sigma`, `w_calib`) and corridor bands—it is possible to formally prove that the addition of this new risk plane preserves the Lyapunov properties of the system. The proof is straightforward: since the new terms are quadratic and weighted with positive weights, they only add a non-negative value to the residual. Therefore, if a control step was Lyapunov-stable before, it remains so after including the data-quality plane. This mathematical guarantee is essential for certification.

Furthermore, this integration creates a powerful fail-safe mechanism. A scenario can be envisioned where all primary risk planes (`r_energy`, `r_carbon`, `r_materials`, etc.) are within their safe bands, suggesting the system is operating normally. However, if sensor drift causes `rsigma` to rise into the 'Hard' band, the `EcoSafetyKernel` will detect this. Because the Lyapunov condition ($V_{t+1} \leq V_t + \epsilon$) depends on the total residual, an increase in `rsigma²` will cause `V_{t+1}` to increase even if all other risk coordinates remain constant. This can easily violate the Lyapunov inequality, triggering a `Derate` or `Stop` decision from the kernel. This behavior is highly desirable: it forces the system to either correct the sensor issue or shut down, rather than continuing to operate based on potentially unreliable data. The `rcalib` score can play a similar role, forcing a system shutdown if a critical sensor has not been recently calibrated.

The implementation of this plane follows the same pattern as the others: executable artifacts and certifiable documentation. The executable component would be a Rust module, `DataQualityMonitor`, that ingests data from the `qpudatashardwriter` and computes the `rsigma` and `rcalib` coordinates. It would also contain the logic for updating the Lyapunov residual to include these new terms. Unit tests would verify that the inclusion of these terms does not break the core assumptions of the Lyapunov framework.

The documentation for this plane is particularly important for explaining its fail-safe role. It should clearly articulate the mathematical proof that adding the new terms preserves

Lyapunov stability. It should also provide examples of how a violation in the data-quality plane can lead to a `Derate` or `Stop` decision, even with nominal primary risk coordinates. Hex-stamped links would connect this explanation to the specific lines of code in `ecosafety-core` that define the residual formula and the `DataQualityMonitor` module that implements the kernel. By treating data quality as a first-class citizen in the risk calculus, the Cyboquatic framework gains a crucial layer of resilience against the inevitable presence of uncertainty in any real-world industrial system.

Component	Description	Rationale & Implementation
`rsigma` Coordinate	Normalized measure of sensor noise, calculated as the standard deviation of a sensor's output over a rolling window.	Directly quantifies signal instability. High `rsigma` indicates potential sensor malfunction or environmental interference.
`rcalib` Coordinate	Normalized score based on a sensor's calibration history (time since last cal, frequency of adjustments).	Reflects the long-term accuracy and trustworthiness of a sensor's measurements.
Lyapunov Integration	Add weighted terms `w_sigma <em> rsigma²` and `w_calib </em> rcalib²` to the total residual V_t.	Formal proof shows that adding these positive terms preserves Lyapunov stability. The weights tune the severity of the penalty.
Fail-Safe Mechanism	A violation in `rsigma` or `rcalib` can cause the total Lyapunov residual `V_t` to increase, potentially triggering a `Derate` or `Stop`.	Ensures the system responds to data unreliability, even if all other risk planes are nominal. Prevents operation on "garbage in".
Executable Artifact	Non-actuating Rust module (`DataQualityMonitor`) computing `rsigma`/`rcalib` and integrating with the Lyapunov residual calculation.	Consumes ingest-quality data from shards and feeds it into the core safety logic.
Cert-Ready Documentation	Hex-stamped proof of Lyapunov preservation and explanation of the fail-safe logic.	Auditable evidence that the data-quality plane is mathematically sound and serves a critical safety function.

Consolidation Strategy: Unifying Code and Schema for Certified Verification

The successful advancement of the Cyboquatic ecosafety framework hinges on a coherent consolidation strategy that unifies disparate codebases and data schemas into a single, auditable, and certifiable entity. The user's directive emphasizes a 30/70 split, dedicating a portion of the effort to freezing and documenting the existing "spine" before focusing on the intensive development of the physics-grounded kernels . This phased approach ensures that the foundational grammar of the framework is stable and well-understood before building upon it. The ultimate goal is to produce dual-form outputs—cert-ready documentation with hex-stamped proofs and executable verification artifacts—that can

be integrated into a CI pipeline, thereby transforming the framework from a collection of independent modules into a cohesive, verifiable system.

The immediate priority is to freeze the `cyboquatic_ecosafety_core` Rust crate as version `v2.0.0` . This crate currently serves as the spine, exporting the fundamental types like `RiskCoord`, `Residual`, `Weight`, the `RiskVector` struct, the `LyapunovWeights` struct, and the `EcoSafetyKernel` logic . Freezing it establishes a single source of truth for the entire risk vocabulary. All other Cyboquatic and EcoNet crates that make safety-related decisions must then be refactored to depend on this core crate. This dependency injection enforces a strict contract: any component that wishes to participate in the safety decision-making process must do so using the standardized types and interfaces defined in `ecosafety-core`. This eliminates ambiguity, prevents the introduction of unsafe primitives, and ensures that all parts of the system speak the same "risk language," a key requirement for achieving a high Knowledge-factor ($K \approx 0.94$) .

Parallel to this code consolidation, the corresponding ALN schemas must be updated and aligned. The existing `corridors` and `riskvector` schemas need to be finalized and versioned (e.g., `ecosafety.corridors.v2`, `ecosafety.riskvector.v2`) . These schemas define the ledger-level rules that govern what data is permissible. They must be kept in sync with the Rust types in `ecosafety-core`. For example, if a new risk plane like `r_biodiversity` is added to the `RiskVector` struct in Rust, the `riskvector` ALN schema must be updated to include this new field. The `writepolicy` section of these schemas, which contains the logical gates like `gate_kinetics` and `gate_KER`, must also be meticulously maintained to reflect the latest corridor band values and aggregation logic . This tight coupling between the runtime code and the static ledger schema is what enables ledger-grade traceability and enforcement of ecological safety policies.

With the unified foundation in place, the intensive development phase can proceed for each of the five risk planes (Carbon, Materials, Biodiversity, Hydraulics, Data-Quality). For each plane, the "highest-yield kernels" identified in the preliminary analysis must be implemented as non-actuating, pure Rust libraries . These libraries will contain the physics-grounded kernels, calibration scripts, and, most importantly, the unit tests that serve as formal proofs of monotonicity and correctness. The calibration scripts are a critical executable artifact; they will take Phoenix pilot data and other empirical sources as input and generate the numerical values for the corridor bands (e.g., `t90_max_days`, `HLR_hard`) that are then consumed by the main safety logic . This separates the empirical calibration work from the deterministic safety logic, making the system transparent and reproducible.

The final, and perhaps most valuable, outcome of this entire process is the generation of cert-ready documentation. This is not a separate activity but an intrinsic part of the development workflow. For every new kernel, formula, or corridor value, a corresponding entry must be created in a master documentation repository. Each entry must be hex-stamped, creating an immutable cryptographic link to the precise commit and line of code in the Rust repository and the row in the ALN schema file . This creates an unbreakable chain of evidence. For example, the proof that the carbon plane kernel maintains Lyapunov stability would be linked to the `lyapunov_residual` function in `lib.rs` and to the definition of the `w_carbon` weight in the `ker_weights.aln` file. This documentation serves as the official certificate, providing auditors and regulators with the definitive record of how the system was designed, why its parameters were chosen, and how its safety properties were formally verified. By combining executable verification modules that can be run by a CI server with this rigorous, hex-stamped documentation, the Cyboquatic project can achieve its ultimate goal: deploying industrial machinery that is not only efficient and restorative but is also demonstrably and verifiably safe.
