From Empirical Data to Ecological Safety: A Unified Framework for Optimizing Circular Hardware Loops in Aquatic Systems

The Foundational Pillars: Empirical Data Generation for Risk-Based Control

The efficacy and safety of an integrated circular hardware loop are fundamentally dependent on two foundational pillars of empirical research: biomechanical kinetics on biodegradable substrates and the creation of canal/sewer decay and fouling atlases. These pillars are not merely preliminary studies but are the very source of the quantitative data that will govern the entire operational life of the system. They transform abstract design principles into provable, computationally enforceable rules, ensuring that all subsequent actions, from material selection to real-time control, are anchored in verifiable environmental performance. The first pillar focuses on the intrinsic properties and behavior of the core material—the biodegradable substrate—under realistic conditions. The second pillar addresses the dynamic and heterogeneous nature of the receiving environment, providing the contextual intelligence required for adaptive and location-specific operation. Together, they form the bedrock upon which a robust, scalable, and ecologically safe water management system can be built.

The first pillar, biomechanical kinetics on biodegradable substrates, involves a rigorous, multi-parameter investigation into how materials like FlowVac-style biopolymer/biochar media behave when deployed in canal, sewer, and river systems . The objective is to move beyond theoretical assumptions and establish a comprehensive database of kinetic parameters that can be encoded as hard constraints within the system's control logic . Key metrics derived from this research directly inform the system's Risk-of-harm (R) score and its Knowledge-factor (K) by quantifying potential pathways of failure. One critical parameter is **rmassloss**, which measures the rate at which the substrate itself degrades . This is vital for confirming that the material fulfills its purpose as a temporary capture medium and does not become a persistent pollutant itself. Studies on the biodegradation of plastic wastes provide relevant models for such investigations [5] . Another crucial

metric is **rleach-tox**, which quantifies the toxicity of any chemicals released during the degradation process . This requires standardized testing protocols, potentially aligned with ISO or OECD guidelines for assessing health risks associated with reclaimed water or waste products [57] [64]. Preventing secondary pollution from the substrate is paramount to achieving the desired low-risk profile. Furthermore, the research must explicitly address **rmicroplastics**, assessing whether the biodegradation of the substrate could inadvertently fragment into microplastics, thereby exacerbating an existing environmental problem [2] [39]. Given the prevalence of microplastics in rivers and their transport mechanisms, this is a non-trivial concern [35] [38]. Finally, the fate of captured pollutants must be tracked through parameters like **rleach-CEC**, which monitors the release of Contaminants of Emerging Concern (CECs) and PFAS from the substrate into the water column [6] [48]. The goal is to ensure these hazardous substances are either destroyed or permanently immobilized within the substrate matrix, rather than being transferred from one environmental compartment to another. The overall degradation kinetics, influenced by factors like temperature, pH, and microbial activity, dictate the efficiency of converting captured organic matter, including FOG, into benign end products like soil-compatible pellets [65] [67] [75].

The second foundational pillar is the development of district-scale "canal/sewer decay and fouling atlases" . These atlases function as dynamic, spatially explicit maps of the hydraulic, chemical, and biological conditions within a given drainage network or river reach. Unlike static design assumptions, these atlases are populated through targeted field campaigns and continuous monitoring, capturing the inherent variability of real-world systems [32] [50]. Their primary components include hydraulic parameters such as flow velocity, turbulence intensity, and residence time, all of which critically influence both the transport of pollutants and the contact efficiency between contaminants and the biodegradable substrate [7] [11] [38]. For instance, higher turbulence can increase mass transfer rates but also shear forces, which may impact biofilm integrity [38]. Chemical parameters are equally important, encompassing concentrations of dissolved oxygen, nutrients, hydrogen sulfide (H_2S), and various metals [13] [15] [33]. High levels of sulfate-reducing bacteria, often indicated by elevated H_2S, signal zones prone to bio-corrosion, a key degradation mechanism in concrete sewers [28] [47]. Biological parameters captured in the atlas include the density and composition of native biofilms, their intrinsic metabolic rates, and local decay constants [74] [78]. Biofilms are central to the natural self-purification capacity of waterways, and understanding their state is essential for predicting system response [79]. By encoding these parameters into a machine-readable format, the atlas provides the contextual intelligence that allows the hardware loop's controller to make informed, localized decisions. Instead of applying a uniform treatment strategy, the system can dynamically adjust its operation—for example, by altering recirculation

patterns or directing specific loads—to optimize performance and mitigate risks based on the precise conditions of the local reach. This capability is fundamental to meeting the project's optimization goals, particularly the drive to lower ecological risk (R) and improve efficiency across diverse and complex environments .

Parameter Category	Specific Metric / Variable	Description and Relevance
Biomechanical Kinetics	rmassloss	Rate of substrate mass reduction; ensures the material is truly biodegradable and doesn't persist as waste .
	rleach-tox	Toxicity of chemicals leached during degradation; prevents secondary pollution and is a key input for the Risk score [57] .
	rmicroplastics	Formation of microplastics during substrate breakdown; critical for preventing unintended environmental harm [2] [39] .
	rleach-CEC	Release of captured Contaminants of Emerging Concern (CECs) and PFAS; ensures pollutants are immobilized or destroyed [6] [48] .
	Degradation Efficiency	Overall rate of FOG/organic matter breakdown; directly linked to the loop's primary function and efficiency [65] [67] .
Decay & Fouling Atlas	Hydraulic Parameters	Includes flow velocity, turbulence, and residence time, which affect pollutant transport and contact with substrates [7] [11] [38] .
	Chemical Parameters	Covers dissolved oxygen, nutrient levels, pH, sulfides (H_2S), and heavy metals, influencing microbial activity and corrosion [13] [15] [33] .
	Biological Parameters	Encompasses biofilm density, microbial community composition, and intrinsic decay rates, indicating the system's baseline health [74] [78] .

Governing the Loop: Eco-Corridors, LCA Gates, and FOG-Aware Routing

Once the foundational data from biomechanical kinetics and decay/fouling atlases is generated, it is not stored as passive information but is actively synthesized into a dynamic governance framework that dictates the behavior of the integrated hardware loop. This framework is built upon three interconnected layers of control: primary "hard eco-corridors," secondary LCA corridors for sustainability, and intelligent FOG-aware routing predicates. The hard eco-corridors represent the most critical layer, serving as provable, mathematically defined boundaries for safe operation. They are the direct output of the foundational research, transforming empirical data into executable code. On top of this risk-based foundation, LCA corridors and FOG-aware routing introduce further layers of optimization, enhancing the system's efficiency and sustainability without compromising its core safety guarantees. This multi-layered, constraint-based

architecture is designed to ensure that every action taken by the hardware is a deliberate, risk-informed decision, enabling the system to achieve its ambitious performance targets.

The cornerstone of the governance structure is the establishment of "hard eco-corridors." These are not soft policy guidelines but rigid mathematical constraints enforced in real-time by the system's central controller, likely implemented using a formal methods language like Rust/ALN . The corridor tables, derived directly from the biomechanical kinetics and decay atlas research, define the permissible operating space for the hardware . Any potential action, such as increasing pump speed or diverting flow, is first simulated against these corridors. If the action would cause a system variable to cross its boundary—a violation of a normalized risk coordinate r_x or a Lyapunov residual V_t—the actuator is simply not engaged . This makes ecological safety a provable invariant of the system's design rather than a hope contingent on operator discretion or post-facto compliance checks . The Lyapunov residual, V_t, serves as a measure of the system's stability, ensuring that operations do not push the local aquatic environment toward an unstable or degraded state . By making these corridors "hard gates," the framework effectively prevents entire classes of unsafe deployments from ever running, fundamentally changing the approach to environmental risk management in engineered water systems . The initial research-only scores for the underlying ecosafety grammar already demonstrate the value of this approach, with a K=0.94, E=0.90, and R=0.12, showing that even before specific hardware is considered, tightening these kernels improves the entire ecosystem's safety profile .

Upon this bedrock of ecological safety, a second layer of optimization is applied through tightened Life Cycle Assessment (LCA) corridors . This layer specifically addresses the "circular" aspect of the hardware loop, focusing on the embodied impacts of the physical components themselves. Before any module—such as a pump, turbine, or sensor rack—is approved for deployment, it must meet strict baselines for Global Warming Potential (GWP) and embedded energy, measured against a global baseline [75]. This LCA data feeds directly into shard fields and contracts, creating a hard build gate . Non-refurbishable hardware or components with excessive embedded impacts simply cannot be approved for use. This ensures that the pursuit of circularity is genuinely sustainable and contributes positively to the system's overall eco-impact (E) score. Research in this area aims to calibrate LCA corridors for FOG/canal hardware loops operating in corrosive environments, pushing the E-score for circular hardware towards its target of 0.93 while driving down the R-score from its current ~0.16 by eliminating high-impact designs from consideration . This focus on Design-for-Disassembly and required refurbishment paths is a core tenet of the cyboquatic hardware philosophy, aiming to save up to 60-80% of the manufacturing energy compared to new builds [75].

A third, equally critical layer of governance is provided by FOG-aware workload routing predicates . These intelligent routing algorithms determine where incoming workloads—representing pollutant-laden flows—are directed within the network. The system extends basic predicates like `tailwindvalid`, `biosurfaceok`, and `hydraulicok` with explicit coordinates for Fat, Oil, and Grease (**rFOG**) and solids (**rsolids**) . When a high-load event characterized by a surge in FOG or fine solids is detected, the router consults the decay atlas and the status of its nodes. It then directs this challenging load away from standard bio-filtration zones, which could be overwhelmed, and instead routes it to specialized circular hardware and substrate loops that are designed and calibrated to handle high organic and lipid loads [18]. This intelligent offloading prevents shock loading, stabilizes the conditions for sensitive biological processes, and maximizes the overall breakdown efficiency of the system without requiring the construction of additional, more powerful infrastructure . The eco-impact of this routing is significant, as it avoids unnecessary pumping and bio-contact on suboptimal surfaces, thereby reducing energy consumption and ecological damage before any new machinery is added . This hierarchical control structure, where primary risk gates are never compromised, provides a robust and scalable model for managing complex aquatic systems.

Optimization Hierarchy: Prioritizing Risk Reduction, Efficiency, and Scalability

The design and operation of the integrated circular hardware loop are guided by a strict, three-tiered optimization hierarchy that reflects a deep commitment to ecological prudence and long-term viability. This hierarchy prioritizes safety above all else, followed by performance, and finally by the ability to deploy the solution broadly. The first priority is the minimization of ecological risk (R), treating it as a non-negotiable constraint that defines the absolute boundaries of acceptable operation. Within these safe confines, the second priority is maximizing the upstream particle breakdown efficiency for pollutants like FOG, fines, and microplastics. Only after establishing a robust and reliable method for safe and efficient treatment is the final priority addressed: enabling scalable eco-impact across diverse aquatic environments. This structured approach ensures that expansion and application do not come at the cost of safety or performance, and it provides a clear pathway for maturing the technology from experimental concepts to validated, deployable solutions.

The primary and most stringent optimization criterion is the drive to minimize ecological risk (R). This is not merely an objective but the foundational principle upon which the

entire system is built. The user has specified a clear target: R $\leqslant$ 0.13 for short-term research goals, with a stretch goal of R $\approx$ 0.10–0.11 upon successful field validation . This focus on risk reduction is operationalized through the "hard eco-corridors" discussed previously. Every component of the system, from the biodegradability of the substrate to the routing of influent flows, is evaluated against its potential to cause harm. The biomechanical kinetics research plays a direct role here; for instance, by rigorously testing for leachate toxicity and microplastic formation, the system can eliminate unsafe substrate recipes before they are ever deployed, thus proactively lowering the potential R-score . Similarly, the decay and fouling atlases help identify and avoid areas within a waterway that are already under stress or have high intrinsic risk, preventing the introduction of new disturbances into fragile ecosystems . The entire Rust/ALN controlled framework is designed to keep the system's state variables, represented by the normalized risk coordinates r_x and Lyapunov residuals V_t, well within the established corridors . By making risk a provable invariant of the system's design, the optimization process shifts from reactive compliance to proactive prevention, ensuring that the technology's implementation does less harm than not implementing it at all. This cautious, evidence-based approach to risk management is central to the project's credibility and long-term success.

Once the primary safety constraints are firmly in place, the second priority is to maximize the upstream particle breakdown efficiency. This objective focuses on the core functional purpose of the loop: the effective removal and transformation of pollutants. The system is tasked with breaking down a range of challenging contaminants, including FOG, fines, microplastics, and other CECs . Efficiency in this context is a multifaceted concept. For FOG, it means optimizing the conditions within the circular loop to promote hydrolysis and subsequent biodegradation by microbial communities [18]. For fines and microplastics, it involves maximizing capture efficiency on the biodegradable substrate media and ensuring they are either mineralized or safely encapsulated [38]. The integration of biomechanical kinetics is again critical; by understanding the degradation rates of different organic compounds under various conditions, the controller can modulate hydraulic retention times and other process parameters to maximize conversion efficiency without exceeding the risk corridors [65] [66]. The FOG-aware routing is a key enabler of this efficiency goal. By intelligently diverting high-FOG events to dedicated processing loops, the system prevents the inhibition or washout of microbes in downstream units, ensuring that all parts of the network are operating at or near their peak effectiveness . The knowledge factor (K) and eco-impact (E) scores reflect this dual focus on safety and performance. For example, refining the biomechanical kinetics of FlowVac substrates aims to raise the cluster K/E/R scores from approximately 0.88/0.87/0.18 toward 0.92/0.89/0.14, demonstrating a concerted effort to improve

both the technical understanding (K) and the practical effectiveness (E) of the treatment process while simultaneously lowering risk (R) .

The final optimization criterion is the scalability of the eco-impact across diverse aquatic environments, including canals, sewers, and rivers. This goal is achieved not by creating multiple bespoke systems, but by developing a consistent and reusable framework. The core of this scalability lies in preserving the same universal rx/Vt grammar and K/E/R gating thresholds across different sites . The adaptation to a new environment, such as a desert city basin versus a temperate river system, is handled primarily by populating the system's "canal/sewer decay and fouling atlases" with local, site-specific data . The underlying control logic, safety protocols, and performance metrics remain constant. This modular approach allows the system to leverage a proven, validated set of rules while still accounting for the unique hydraulic and biological characteristics of each deployment location. The ultimate aim is to create a platform where once a particular combination of hardware, substrate, and routing logic has been field-validated and shown to perform reliably within its K/E/R targets, it can be confidently replicated elsewhere. This standardization is what enables the technology to transition from isolated pilot projects to widespread deployment, maximizing its positive eco-impact on a larger scale. The optimization path is therefore clear: first, establish a safe and efficient prototype; second, validate it in the field; and third, reuse the validated rx/Vt grammar and K/E/R gates to rapidly and safely deploy the solution to new locations, building on a foundation of proven performance and safety.

Performance Benchmarks and Field Validation Pathways

The development and deployment of the integrated circular hardware loop are guided by a set of explicit, quantitative performance benchmarks expressed through the K/E/R scoring system. These scores provide a common language for evaluating progress and success across different research lines and components of the system. The overarching goal is to evolve the system's performance from its current research-only estimates toward more mature, field-validated targets. Achieving these benchmarks is contingent on a structured pathway of field validation, which involves iterative testing, refinement, and calibration of the system's core models and control logic. This empirical validation is the only way to bridge the gap between theoretical performance and real-world reliability, ensuring that the system can consistently deliver its promised benefits in terms of reduced ecological risk and enhanced pollutant breakdown.

The performance of the integrated loop is assessed using a composite K/E/R score, which balances Knowledge acquisition, Eco-impact, and Risk-of-harm . The table below presents the current research-only scores for the constituent parts of the proposed system, along with the target scores for the integrated loop family. This highlights the intended improvement and synergy when the components are combined and optimized together.

Cyboquatic Research Line	K (Knowledge)	E (Eco-Impact)	R (Risk-of-Harm)
Ecosafety Grammar Spine (r_x, V_t)	0.94	0.90	0.12
MAR Cyboquatic Modules (Desert Basins)	0.93	0.92	0.14
Ecotechnology Habitat Repair	0.90	0.91	0.15
Soft-Robotic Nodes	0.88	0.87	0.18
Circular Hardware Refurbishment	0.89	0.88	0.16
FlowVac Biodegradable Substrates	0.88	0.87	0.18
FOG Energy-Biosafe Routing	0.93	0.90	0.14

The target for the integrated "circular hardware + FlowVac substrates + FOG routing + decay atlases" system is a cluster band of Kcluster ≈ 0.91–0.92, Ecluster ≈ 0.89–0.90, and Rcluster ≈ 0.14–0.15 . The short-term goal is to tighten these targets to K ⩾ 0.93, E ⩾ 0.90, and R ⩽ 0.13 . The ultimate stretch goal, achievable only after comprehensive field validation of the decay kinetics, leachate corridors, and FOG routing logic, is to push the cluster toward K ≈ 0.95, E ≈ 0.92, and R ≈ 0.10–0.11 . These targets are not arbitrary; they represent a systematic progression toward a safer, more efficient, and more impactful technology. The reduction in R from ~0.14 to <0.13, and eventually to 0.10-0.11, is the primary driver and signifies a major leap in the system's safety and reliability. The corresponding increases in K and E reflect the deeper understanding and greater practical effectiveness unlocked by this improved safety.

Achieving these targets requires a disciplined pathway of field validation. The process begins with lab-scale experiments on biodegradable substrates to generate the initial biomechanical kinetic data . This is followed by pilot-scale deployments in representative canal, sewer, or river segments. These pilots are not just demonstrations of function but are critical data collection missions. During these trials, the system's controllers, using the initial corridor definitions, will be tested under real-world conditions. The Lyapunov residuals (V_t) and risk coordinates (r_x) will be continuously monitored to assess if the theoretical corridors accurately predict real-world system behavior. Any discrepancies will trigger a feedback loop: the raw data from the field is used to refine the predictive models in the biomechanical kinetics research and the decay/fouling atlases . For example, if the system experiences unexpected clogging in a certain type of pipe, the decay atlas model for that reach will be updated to better reflect the local fouling

propensity. Similarly, if a particular substrate recipe shows slower-than-predicted degradation or releases unexpected compounds, its shard contract will be revised or it will be deprecated. This iterative cycle of deployment, monitoring, analysis, and refinement continues until the system's performance consistently meets or exceeds the short-term targets. Only after multiple successful pilots across different environments have validated the core models can the stretch goals of $R \approx 0.10–0.11$ be pursued with confidence. This empirical validation is the only rigorous method to build trust in the system and justify its wider deployment, ensuring that the positive eco-impact is genuine and sustained.

Strategic Synthesis and Future Research Directions

In synthesis, the proposal for an integrated circular hardware loop represents a sophisticated and scientifically grounded paradigm for next-generation water management. Its core strength lies not in the invention of a single novel technology, but in the elegant and rigorous integration of disparate fields—biomechanics, environmental hydraulics, computational control theory, and life cycle assessment—into a single, cohesive, and provably safe system. The strategic vision is to move beyond linear, end-of-pipe treatment models toward a dynamic, risk-aware, and resource-efficient operational framework. The immediate future of this research hinges on the disciplined execution of a plan that prioritizes empirical data generation, formalizes this data into computationally enforceable rules, and validates the resulting system through iterative, real-world testing. Success will depend on the seamless interplay between foundational science and advanced engineering, ultimately leading to a scalable solution for mitigating pollution in critical aquatic ecosystems.

The most critical strategic imperative is to prioritize the foundational research pillars: biomechanical kinetics on biodegradable substrates and the development of canal/sewer decay and fouling atlases . Without the rich, empirically-derived datasets from these areas, the entire governance structure of hard eco-corridors lacks its essential grounding. The research program must proceed with a clear protocol: systematically test a portfolio of biopolymer/biochar substrate recipes under a range of simulated and real-world conditions to generate the kinetic parameters of mass loss, leachate toxicity, microplastic formation, and contaminant fate . Simultaneously, district-scale campaigns must be launched to collect the high-resolution hydraulic, chemical, and biological data needed to construct accurate decay and fouling atlases . These two streams of data are the inputs that will fuel the system's intelligence. Concurrently, efforts must accelerate to develop

the unified eco-corridor grammar and codify the relationships between the kinetic data, atlas data, and the resulting control variables (r_x, V_t) into machine-readable shard contracts, likely leveraging the safety guarantees offered by a language like Rust/ALN . This formalization is what transforms data into actionable control logic.

Following the completion of this foundational work, the focus must shift to iterative field validation. The short-term K/E/R targets (K ⩾ 0.93, E ⩾ 0.90, R ⩽ 0.13) and the aspirational stretch goals (R ≈ 0.10–0.11) are not mere aspirations but are concrete milestones that must be earned through rigorous testing . Pilot projects should be deployed in a variety of representative environments—a concrete sewer, a brick-lined canal, and a natural river section—to test the adaptability of the system. These pilots will serve to tune the corridor models, validate the efficacy of the FOG-aware routing logic, and refine the LCA data for different operating contexts. The learning from these pilots is invaluable; for example, they can reveal unforeseen interactions, such as the effect of specific industrial discharges on substrate degradation or the long-term impact of recycled pellet deposition on benthic environments. Each iteration brings the system closer to its full potential, transforming it from a promising concept into a trusted and deployable technology.

Ultimately, the long-term success and scalability of the integrated circular hardware loop will be determined by its ability to maintain a consistent, validated core while adapting to local conditions. The strategy for achieving this is clear: the fundamental rx/Vt grammar and K/E/R thresholds must remain fixed, acting as the immutable "spine" of the system . Adaptation to new sites should occur primarily through the population of the "canal/sewer decay and fouling atlases" with local data, rather than through modifications to the core control logic . This modular, standardized approach is the key to unlocking large-scale deployment. By reusing a proven and validated set of rules, the barriers to entry for deploying the technology in a new city or watershed are significantly lowered. The future direction of this research, therefore, is not about reinventing the wheel for each new application, but about perfecting the wheel and the roadmaps (atlases) that guide it. This focused, evidence-based, and hierarchically organized approach provides a clear and powerful pathway toward realizing a tangible, positive, and scalable eco-impact.
